

General Framework for a Backtracking Algorithm

- let us assume that the solution takes the form

$$x[1], x[2], \dots, x[n]$$

where $x[i] \in S$

Observation: in the n queens problem $S = \{1, 2, 3, \dots, n\}$

backtrack(n)

$\text{rbacktrack}(1, n)$

$\text{rbacktrack}(k, n)$

 for each $x[k] \in S$

 if $\text{bound}(k) == \text{true}$

 if $k == n$

 output a solution; stop here if only one solution is desired

 else // $k < n$

$\text{rbacktrack}(k+1, n)$

$\xrightarrow{\hspace{1cm}}$
 $x[1], x[2], \dots, x[k], \dots, x[n]$

$\text{bound}(k)$

// give pseudocode implementation

• function $\text{bound}(k)$

- assume that $x[1], x[2], \dots, x[k-1]$ is a partial feasible solution and that $x[k]$ has been assigned some value

- return $\begin{cases} \text{true} & \text{if } x[1], x[2], \dots, x[k] \text{ is a partial feasible solution} \\ \text{false} & \text{otherwise} \end{cases}$

• goal: design an efficient $\text{bound}()$ function to eliminate many potential nodes (i.e. nonpromising nodes) from the search tree.
